Acid-Base Balance in Artificially Respired Guinea-Pigs under Normal Conditions and During Exposure to Hyperbaric Helium

Certain drug evaluation procedures being used in this laboratory necessitate the use of artificial respiration of guinea-pigs during exposure of the animals to a hyperbaric helium atmosphere. In order to ascertain that the artificial ventilation maintained normal acid-base balance, arterial blood pH was measured in guinea-pigs during artificial respiration either at normal or elevated pressure. In animals respired at normal pressure, arterial blood pO₂ and pCO₂ were also measured. The pH and gas values were compared with values found in unanesthetized and in anesthetized, non respired animals. The values for pH and pCO₂ determined for normal animals were not in good agreement with previously reported values!

Four groups of male guinea-pigs of the NMRI (H) strain, weighing 302-500 g, were used. In group I (normal, unanesthetized), a length of PE-50 tubing was inserted in the carotid artery while the animals were under light ether anesthesia. 4 h following recovery from anesthesia, carotid artery blood samples were drawn for analysis. In group II, animals were anesthetized with Dial-urethane sontion (6 6 ml/kg, i.p.) and the catotid artery was cannulated as in the first group. Duration of anesthesia was greater than the remainder of the experiment, and arterial blood samples were drawn 4 h after completion of surgery. Groups III-A and III-B (artificially respired animals exposed to normal or high pressure, respectively) were treated in the same manner as animals in group II, but, in addition, the trached was cannulated and the animals were connected to a

piston-type small animal respirator with inflation volume set to provide an inflation pressure of 65 mm $\rm H_2O_{\odot}$

The respirator was set at a rate that just prevented animals from breathing spontaneously, and this rate was deverning by trial and error for each animal. The suppression of spontaneous respiration was considered to result primarity from operation of an inhibitory respiratory relies (Hering-Breuer inflation reflex). The possibility that hyperventilation contributed to the suppression cannot be totally ruled out, but this contribution must have been quite small in view of the normal arterial blood pH values subsequently measured in these animals.

Blood samples from animals in group III-A were obtained after 1 and 4 h of artificial respiration, Animals in group III-B were pressurized in a hyperbaric chamber 2 to a total pressure of 282 Ψ (final composition of the hyperbaric atmosphere was pHe = 19.0 atm.; pO₂ = 0.2 atm.) Blood samples from animals of group III-B were obtained 1 and 4 h after pressurization. Gas and pH values for group III-A, and pH values for group III-B, measured in

the 1-hoer sample, served as a guide for adjusting the rate of artificial respiration for the remainder of the experiment.

Blood pH, pCO2, and pO2 were measured with an Instrumentation Laboratories Model 113 analyzer. In animals of group III-B, only pH could be measured accurately because effervescence in decompressed blood interfered with measurement of pCO_2 and pO_2 . A 2-ml sample of bio "was sufficient for the analyses, Results for the 4 groups of animals are shown in the Table. The data demonstrate that mesthesia significantly depressed respiration in spontaneously breathing guinea-pigs (group 11) as compared with normal animals (group 1). However, the Table also shows that the artificial respiration used in these studies (groups 111-A or 111-B) successfully reversed the respiratory depression and maintained the animals in normal acid-base balance. Apparently, artificial ventilation was not appreciably affected by the use of a gas mixture that was approximately 2.9 times as dense as air at a pressure of 1 atm.

It is interesting to compare the present data with previously published values for pH and pCO₂ in guinea-pigs, also given in the Table. Currently cited values for normal guinea-pigs¹ are based on the work of Hawxins³, who analyzed blood obtained by cardiae puncture, using the Van Slyke method to determine total CO₂, and a comparator block method to estimate pH. Results obtained with cardiae juncture blood should be interpreted with cardiae juncture blood, should be interpreted with cardiae juncture of the likelihood of aspirating a mixture of arterial and cenous blood. The Table shows that Hawkins reported nearly the same pCO₂, but a much lower pH than was found in the present study.

In conclusion, the present data demonstrate that artificial respiration of guirea-pigs, as performed in this labofatory, provided adequate vanifiation of the animals, both at normal pressure and in a hyperbaric helium atmosphere. In addition, the pH and pCO₂ reported here for unanesthetized animals may be closer to true values for normal guinea-pigs than are the currently cited values^{2,5}

Ausaumenfassung. Säure-Basen-Werte von Meerschweinchen (Cavia porcellus L.) wurden unter künstlicher Atmung bei normalem Druck und bei Druck von 19.2 Atm. gemessen und festgestellt, dass künstliche Atmung unter erhöhtem Druck normale Säure-Basen-Gleichgewichte gewährleistet, während die Säure-Basen-Werte normaler Tiere mit denjemgen der Literatur meht übereinstimmten.
